Counting infinitely by oritatami co-transcriptional folding

Kohei Maruyama · Shinnosuke Seki

Received: date / Accepted: date

Abstract A fixed bit-width counter was proposed as a proof-of-concept demonstration of the oritatami model of cotranscriptional folding [Geary et al., Proc. MFCS 2016, LIPIcs 58, 43:1-43:14], and it was embedded into another oritatami system that self-assembles a finite portion of Heighway dragon fractal. In order to expand its applications, we endow this counter with capability to widen bit-width at every encounter with overflow.

1 Introduction

Counting is one of the most essential tasks for computing; as well known, the ability to count suffices to enable Turing universality [14]. Nature has been counting billions of days using molecular "circadian clockwork" which is "as complicated and as beautiful as the wonderful chronometers developed in the 18th century" [13]. Nowadays, developments in molecular self-assembly technology enable us to design molecules to count. Evans has demonstrated a DNA tile self-assembly system that counts accurately *in-vitro* in binary from a programmed initial count until it overflows [5]. In its foundational theory of molecular self-assembly, such binary counters have been proved versatile, being used to assemble shapes of particular size [1,17], towards self-assembly of fractals [12], and as an infinite scaffold to simulate all Turing machines in parallel in order to prove undecidability of nondeterminism in the abstract tile-assembly model [2], to name a few.

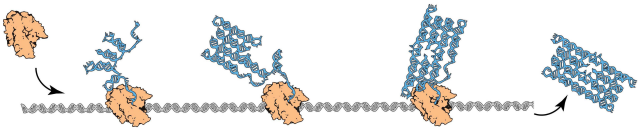

Fig. 1 RNA origami. RNA polymerase enzyme (orange) synthesizes the temporal copy (blue) of a gene (gray spiral) out of ribonucleotides of four types A, C, G, and U.

A fixed bit-width (finite) binary counter has been implemented as a proof-of-concept demonstration of the oritatami model of cotranscriptional folding [8]. As shown in Fig. 1, an RNA transcript folds upon itself while being transcribed (synthesized) from its corresponding DNA template strand. Geary, Rothemund, and Andersen programmed a specific RNA rectangular tile structure into a DNA template in such a way that the corresponding RNA transcript *folds cotranscriptionally* into the programmed tile structure with high probability *in-vitro* at room temperatures (*RNA origami*) [9]. An oritatami system folds a transcript of abstract molecules called *beads* of finitely many types over the 2-dimensional triangular lattice cotranscriptionally according to a rule set that specifies which types of molecules are allowed to bind at the unit distance. The transcript of the binary counter in [8] is of period 60 as ⓪−①−②−$\cdots$−㊽−㊾−⓪−①$\cdots$ and its period is semantically divided into two half-adder (HA) modules A = ⓪−①−$\cdots$−⑪ and C = ㉚−㉛−$\cdots$−㊶ and two structural modules B and D,

An extended abstract on this work was published as a short paper in the proceedings of the 46th International Conference on Current Trends in Theory and Practice of Computer Science (SOFSEM 2020, Limassol, Cyprus, January 20-24, 2020), LNCS 12011, pp. 566–575.

which are sandwiched by half-adder modules along the transcript as $ABCD$. While being folded cotranscriptionally in zigzags, HA modules increment the current count i by 1, which is initialized on a linear *seed* structure, alike the Evans' counter, whereas structural modules B and D align HA modules properly and also make a turn at an end of the count i; B guides the transcript from a zig to a zag ($\hookrightarrow$) while D does from a zag to a zig ($\hookleftarrow$). This counter was embedded as a component of an oritatami system to self-assemble an arbitrary finite portion of Heighway dragon fractal [12]. Its applications are limited, however, by lack of mechanism to widen bit-width; its behavior is undefined when its count overflows. In this paper, we endow this counter, or more precisely, its structural module B, with the capability to widen the count by 1 bit at every overflow.

The oritatami model has been proven Turing universal in [7], where a universal Turing machine is encoded as a seed and a period of transcript of an oritatami system using 542 bead types, and the number of bead types needed for the universality was reduced to almost one-third (183 bead types) recently [16] by an intrinsic simulation of 1-dimensional cellular automata (CA). It is hence no surprise that oritatami systems can count even infinitely. An advantage of the counter we shall propose is that the number of bead types it employs is just 132 and so is the length of a period of its transcript, which is indeed ①−②−$\cdots$−㉜, whereas a period of a transcript to simulate a radius-r CA with Q states by the simplified Turing universal oritatami system is of length about $\frac{142}{3}Q_r^2 \log_2 Q_r$, where $Q_r = 2^{\lceil \log_2 (2Q^{2r+1}) \rceil}$, which is apparently much longer than the period of the proposed counter. A periodic transcript is expected to be transcribed from a circular DNA [6] but such a template DNA sequence gets more costly to be synthesized as it gets longer. Another advantage of the proposed counter is its suppositional compatibility with other oritatami systems, which has been somehow affirmed by the oritatami system for Heighway dragon fractal [12], to which the original fixed bit-width binary counter is embedded to remember how many turns the dragon has made so far.

This paper is organized as follows. In Section 2, we provide basic notions and notation of oritatami system. The infinite counter shall be explained into detail in Section 3. We conclude this paper in Section 4 with a short discussion.

2 Preliminaries

Let Σ be a finite alphabet, whose elements should be regarded as types of abstract molecule, or *beads*. A bead of type $a \in \Sigma$ is called an a-bead. By Σ^* and Σ^ω, we denote the set of finite sequences of beads and that of one-way infinite sequences of beads, respectively. The empty sequence is denoted by λ. Let $w = b_1 b_2 \cdots b_n \in \Sigma^*$ be a sequence of length n for some integer n and bead types $b_1, \ldots, b_n \in \Sigma$. The *length* of w is denoted by $|w|$, that is, $|w| = n$. For two indices i, j with $1 \leq i \leq j \leq n$, we let $w[i..j]$ refer to the subsequence $b_i b_{i+1} \cdots b_{j-1} b_j$; if $i = j$, then $w[i..i]$ is simplified as $w[i]$. For $k \geq 1$, $w[1..k]$ is called a *prefix* of w.

Oritatami systems fold their transcript, which is a sequence of beads, over the triangular grid graph $\mathbb{T} = (V, E)$ cotranscriptionally. A directed path $P = p_1 p_2 \cdots p_n$ in $\mathbb{T}$ is a sequence of *pairwise-distinct* points $p_1, p_2, \ldots, p_n \in V$ such that $\{p_i, p_{i+1}\} \in E$ for all $1 \leq i < n$. Its i-th point is referred to as $P[i]$. Now we are ready to abstract RNA single-stranded structures in the name of conformation. A *conformation* C (over Σ) is a triple (P, w, H) of a directed path P in $\mathbb{T}$, $w \in \Sigma^*$ of the same length as P, and a set of (hydrogen) bonds $H \subseteq \big\{\{i, j\} \bigm| 1 \leq i, i+2 \leq j, \{P[i], P[j]\} \in E\big\}$. This is to be interpreted as the sequence w being folded along the path P in such a manner that its i-th bead $w[i]$ is placed at the i-th point $P[i]$ and the i-th and j-th beads are bonded (by a hydrogen-bond-based interaction) if and only if $\{i, j\} \in H$. The condition $i + 2 \leq j$ represents the topological restriction that two consecutive beads along the path cannot be bonded. A *rule set* $R \subseteq \Sigma \times \Sigma$ is a symmetric relation over Σ, that is, for all bead types $a, b \in \Sigma$, $(a, b) \in R$ implies $(b, a) \in R$. A bond $\{i, j\} \in H$ is *valid with respect to* R, or simply R-valid, if $(w[i], w[j]) \in R$. This conformation C is *R-valid* if all of its bonds are R-valid. For an integer $\alpha \geq 1$, C is *of arity* α if it contains a bead that forms α bonds but none of its beads forms more. By $\mathcal{C}_{\leq \alpha}(\Sigma)$, we denote the set of all conformations over Σ whose arity is at most α; its argument Σ is omitted whenever Σ is clear from the context.

The oritatami system grows conformations by an operation called elongation. Given a rule set R and an R-valid conformation $C_1 = (P, w, H)$, we say that another conformation C_2 is an elongation of C_1 by a bead $b \in \Sigma$, written as $C_1 \xrightarrow{R}_b C_2$, if $C_2 = (Pp, wb, H \cup H')$ for some point $p \in V$ not along the path P and set $H' \subseteq \big\{\{i, |w|+1\} \bigm| 1 \leq i < |w|, \{P[i], p\} \in E, (w[i], b) \in R\big\}$ of bonds formed by the b-bead; this set H' can be empty. Note that C_2 is also R-valid. This operation is recursively extended to the elongation by a finite sequence of beads as: for any conformation C, $C \xrightarrow{R}{}^*_\lambda C$; and for a finite sequence of beads $w \in \Sigma^*$ and a bead $b \in \Sigma$, a conformation C_1 is elongated to a conforma-

tion C_2 by wb, written as $C_1 \xrightarrow{R}{}^{*}_{wb} C_2$, if there is a conformation C' that satisfies $C_1 \xrightarrow{R}{}^{*}_{w} C'$ and $C' \xrightarrow{R}_{b} C_2$.

An *oritatami system* Ξ is a tuple $(\Sigma, R, \delta, \alpha, \sigma, w)$, where Σ and R are defined as above, while the other elements are a positive integer δ called *delay*, a positive integer α called *arity*, an initial R-valid conformation $\sigma \in C_{\leq\alpha}(\Sigma)$ called the *seed*, and a (possibly infinite) *transcript* $w \in \Sigma^* \cup \Sigma^\omega$, which is to be folded upon the seed by stabilizing beads of w one at a time so as to minimize energy collaboratively with the succeeding $\delta-1$ nascent beads. The energy of a conformation $C = (P, w, H)$, denoted by $\Delta G(C)$, is defined to be $-|H|$; the more bonds a conformation has, the more stable it gets. The set $\mathcal{F}(\Xi)$ of conformations *foldable* by the system Ξ is recursively defined as: the seed σ is in $\mathcal{F}(\Xi)$; and provided that an elongation C_i of σ by the prefix $w[1..i]$ be foldable (i.e., $C_0 = \sigma$), its further elongation C_{i+1} by the next bead $w[i+1]$ is foldable if

$$C_{i+1} \in \operatorname*{arg\,min}_{\substack{C \in \mathcal{C}_{\leq\alpha}\, s.t. \\ C_i \xrightarrow{R}_{w[i+1]} C}} \min\Big\{ \Delta G(C') \;\Big|\; C \xrightarrow{R}{}^{*}_{\substack{w[i+2\ldots i+k] \\ k\leq\delta, C' \in \mathcal{C}_{\leq\alpha}}} C', \Big\}. \tag{1}$$

Then we say that the bead $w[i+1]$ and the bonds it forms are *stabilized* according to C_{i+1}. Note that an arity-α oritatami system cannot fold any conformation of arity larger than α. A conformation foldable by Ξ is *terminal* if none of its elongations is foldable by Ξ. The oritatami system Ξ is *deterministic* if for all $i \geq 0$, there exists at most one C_{i+1} that satisfies (1). A deterministic oritatami system folds into a unique terminal conformation.

Example 1 (Glider[1]*)* See Fig. 2 for a delay-3 deterministic oritatami system Ξ to fold a motif called a glider. Its transcript is a repetition of $a \bullet bb' \bullet a'$ and its rule set R is $\{(a, a'), (b, b')\}$. Its seed is colored in red. The first 3 beads, $a \bullet b$, are transcribed and elongate the seed in all possible ways. The a-bead cannot bind or the second bead is inert according to R. The third bead, b, can bind to the b'-bead in the seed but for that, the a-bead must be located to the east of the previous a'-bead; it is thus stabilized there. Then the next bead, b', is transcribed. After the three steps, the third bead, b, is stabilized. It is not until then that its bond with the b'-bead is also stabilized.

The glider is self-sustaining and has provided a solid scaffold to oritatami systems [3,4,7,10,16]. Counting infinitely in a zigzag manner requires a self-sustaining structure because while widening bit-width at an overflow, such a counter cannot be bonded to the previous zag (see Figs. 11 and 12). Modules of the fixed bit-width oritatami counter fold into parallelograms. As a rule of thumb, a parallelogram requires such a considerable number of bonds to stand alone that it is not extensible functionally very much. Therefore, we have designed modules of the proposed counter based on a glider (see Figs. 4, 5, 6, and 7).

[1] A video to show how a glider folds can be found at `https://www.dailymotion.com/video/x3cdj35`, in which the Turing universal oritatami system by Geary et al. [7] is running at delay 3.

3 Folding an infinite binary counter

In this section, we describe a delay-3, arity-5 deterministic oritatami system to count infinitely. It employs 132 bead types, and its transcript w is a repetition of `1-2-3-` $\cdots$ `-132`. Its rule set is given in Sect. 3.7. The fixed bit-width counter by Geary et al. [8] operates at delay 4 under a different dynamics, but it was modified in [12] so as to run at delay 3 and under the more prevailing dynamics (1) in the research of oritatami model.

3.1 General idea

Between two consecutive overflows, the proposed system behaves in the same way as the fixed bit-width counter. Its transcript folds in a zigzag manner macroscopically (downward in figures throughout this paper). A zig, folding from right to left, increments the current count by 1. The succeeding zag, folding from left to right, formats the incremented count for the sake of next zig and copies it downward. Unlike the existing counter, when a zig encounters an overflow, it does not abort but rather extends the current count by 1 bit.

The transcript of the proposed counter is periodic. Its period `1-2-3-` $\cdots$ `-132` is divided semantically into the following four subsequences, called *modules*:

`1– 30`	Format module or F; colored in green
`31– 66`	Left-Turn module or L; blue
`67– 96`	Half-Adder module or H; red
`97–132`	Right-Turn module or R; yellow

The transcript can be hence represented as $(\mathrm{FLHR})^*$ at the module level. Modules are to play their roles in expected environments by folding into respective conformations which should be pairwise-distinct enough to be distinguishable by other modules transcribed later. Such expected conformations are called a *brick*. For example, module F encounters the four environments shown in Fig. 4 where it takes the four bricks `Fnt`, `Fnb`,

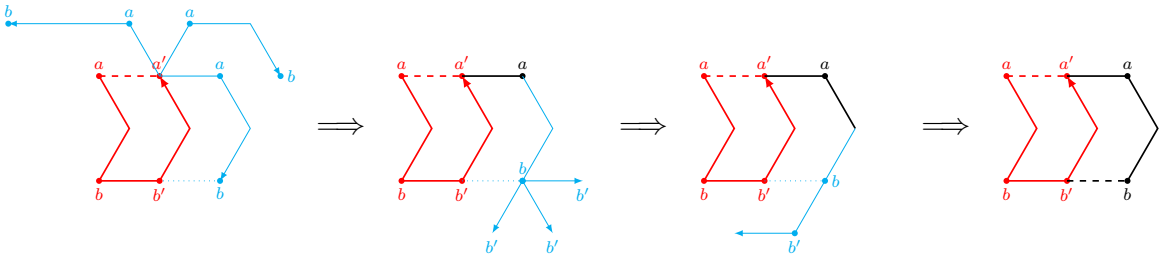

Fig. 2 Folding of a glider motif by a delay-3 deterministic oritatami system.

F0, and F1, respectively. Here, by saying (an instance of) a module folds into (or takes) a brick in an environment, what we actually mean is that the rule set is designed so as for the transcript of the module to interact with itself as well as with the environment into that brick according to the oritatami dynamics (1). The whole system is designed to guarantee that each module is transcribed only in one of the environments it expects. This fact is illustrated in the *brick automaton*, which describes pairs of an environment and a brick as a vertex and transitions between them. Since this automaton is closed, it suffices to test whether for all pairs of an environment and a brick, the brick is folded in the environment. This test has been done *in-silico* using a simulator developed for this project. This brick automaton and all the certificates can be found at `https://komaruyama.github.io/oritatami-infinit-counter/`.

Seed and Encoding. An initial count is encoded in binary as $b_{k-1}b_{k-2}\cdots b_1b_0$ on the seed in the following format:

$$\texttt{64-65-66-}\left(\prod_{i=k-1}^{0}\left(w_{Hn}w_{Rb}w_{Fb_i}w_{Lbn}\right)\right)w_{Hn}, \qquad (2)$$

where

$$\begin{aligned}
w_{Hn} &= \texttt{67-76-77-78-79-88-89-90-91-96},\\
w_{Rb} &= \texttt{97-102-103-108-109-114-115-120-}\\
&\quad \texttt{-121-126-127-132},\\
w_{F0} &= \texttt{1-10-11-12-13-22-23-24-25-30},\\
w_{F1} &= \texttt{1-22-23-24-25-26-27-28-29-30},\\
w_{Lbn} &= \texttt{31-36-37-42-43-48-49-54-55-64-}\\
&\quad \texttt{-65-66}.
\end{aligned}$$

w_{Hn}, w_{Rb}, w_{F0}, w_{F1}, and w_{Lbn} are sequences of bead types exposed downward by modules H, R, F, L when they fold into bricks Hn, Rb, Fb_i, Lbn, respectively, which can be found in Figs. 6, 7, 4, and 5. The seed is exemplified for $k = 1$ and $b_0 = 0$ in Fig. 8 or for $k = 0$ (non-coding, i.e., initial count 0) in Fig. 13, where it is colored in purple.

3.2 Brick level overview

Starting from the seed, this system cyclically transits four phases: zig ($\leftarrow$), left carriage-return ($\hookrightarrow$), zag ($\rightarrow$), and right carriage-return ($\hookleftarrow$). The prefix $(FLHR)^kF$ of the transcript folds into the first zig (recall that k is the bit-width of the initial count). In zigs in general, all the instances of modules F and H fold into bricks of width 10 and height 3, while all the instances of L and R fold into bricks of width 12 and height 3. Zigs thus turn out to be a linear structure of height 3. We can inductively observe that the i-th instance of H in the prefix is transcribed right below b_{i-1} encoded on the seed in the format (2) so that the H can "read" b_{i-1}. After the whole prefix thus has folded into the first zig, the next L is transcribed right below Turn Signal, which lets the L fold into a special brick for left carriage-return if the zig ended at the top (this occurs when $b_{k-1}b_{k-2}\cdots b_0 < 1^k$) (see Fig. 9). We should note that this special brick Lcre is provided with another Turn Signal for the sake of next left carriage-return. Having been thus carriage-returned, the succeeding subsequence $(HRFL)^kH$ of the transcript folds into the first zag. Even in zags instances of F and H fold into bricks of width 10 and height 3, while those of L and R fold into bricks of width 12 and height 3. As a result, zags turn out to be a linear structure of height 3. More importantly, instances of H and F are aligned thus vertically and alternately into columns (see Figs. 8, 9, and 10), i-th of which from the right propagates the $(i-1)$-th bit of the count downward. After the whole subsequence has folded into the first zag, an instance of R is transcribed and folded into a special brick Rcr for right carriage-return due to the turn signal 125-124-123-122, which occurs also at the bottom of Rcr for the sake of next right carriage-return. This amounts to one cycle of the phase transition.

3.3 Increment of the counter

In a zig, module H plays its primary role as a half-adder and carry transfers through instances of others

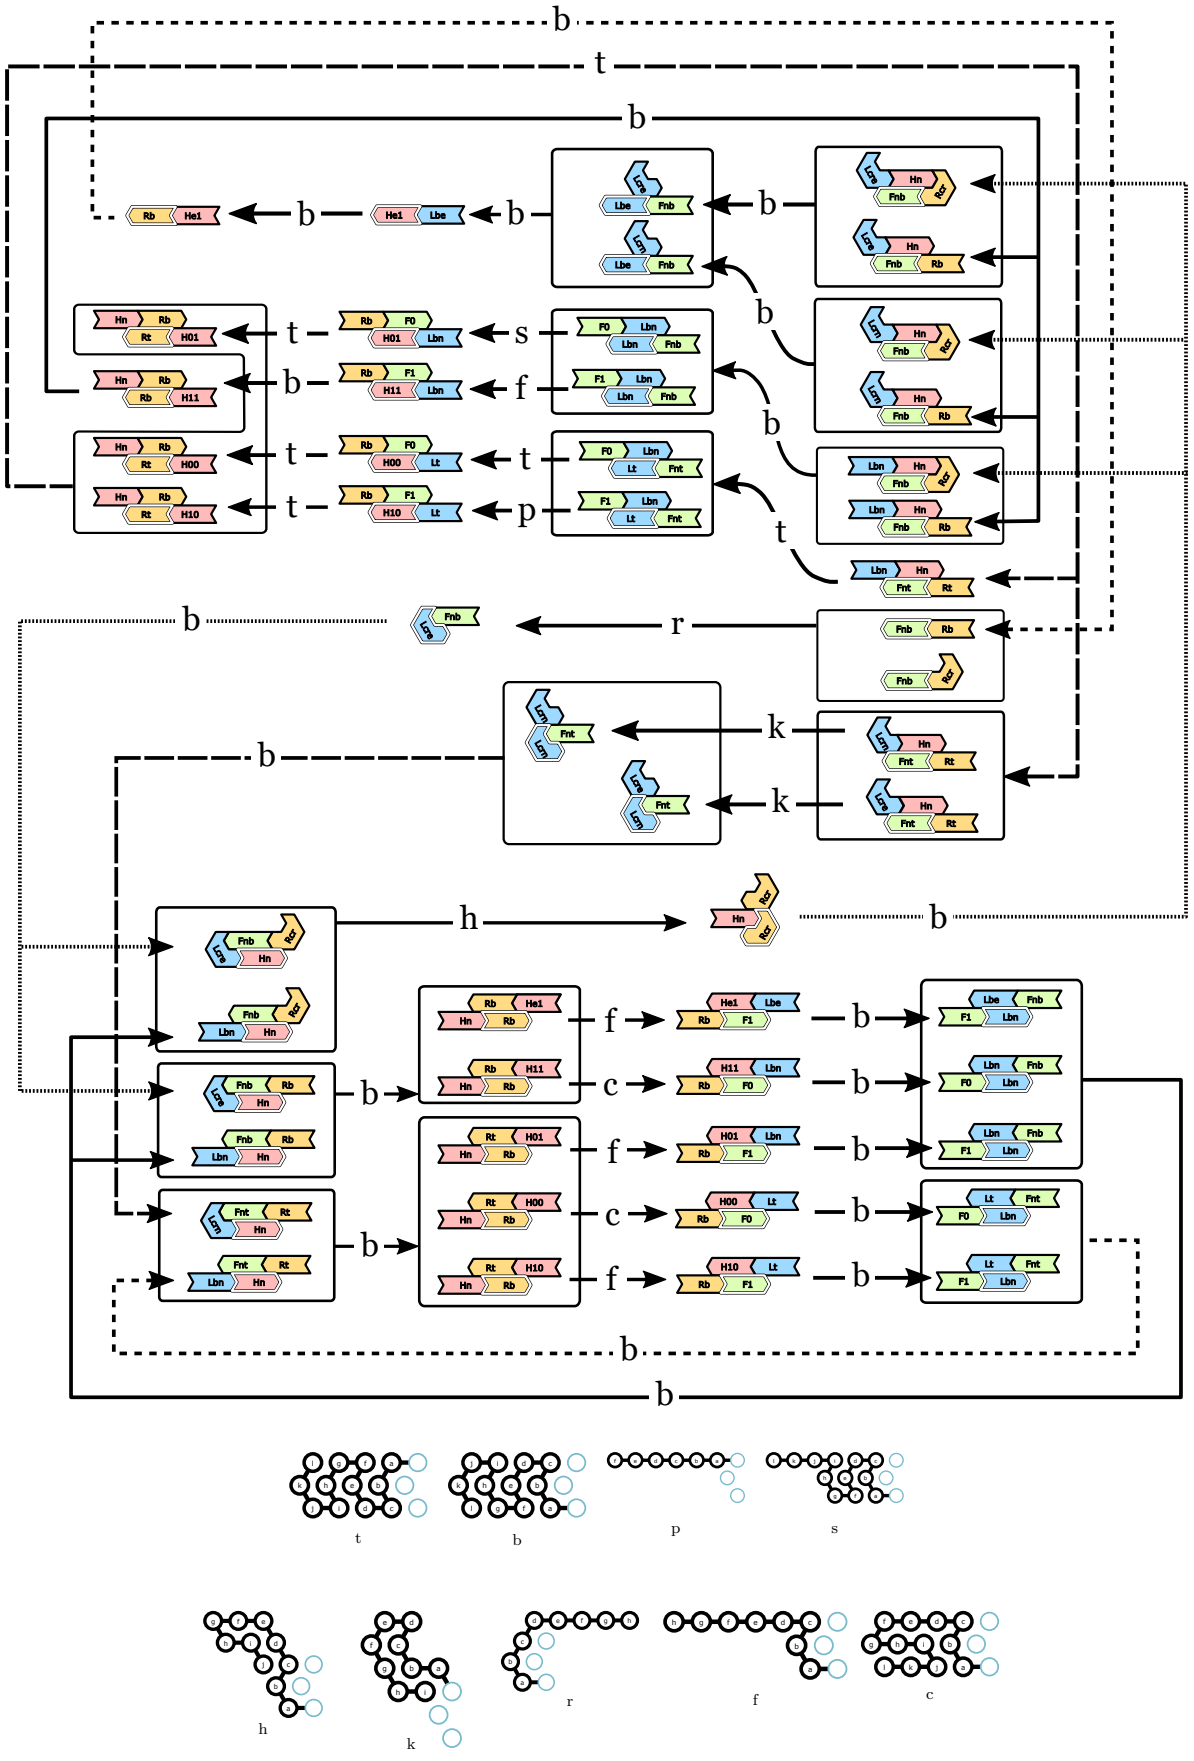

Fig. 3 A brick automaton of the proposed infinite binary counter. 9 possible ways of folding the first several beads of a module being transcribed are enumerated at the bottom with labels t, b, . . . , and transitions in the brick automaton are labeled with a corresponding way of folding

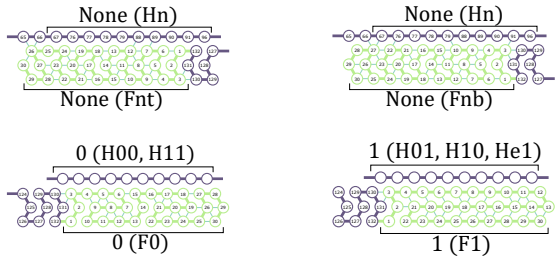

Fig. 4 All the four bricks of module F: The two bricks at the top, `Fnt` and `Fnb`, are for zigs while the others, `F0` and `F1`, are for zags. `Fnb` binds to the zag above so weakly that it can fold even in the absence of such a zag, that is, at an overflow.

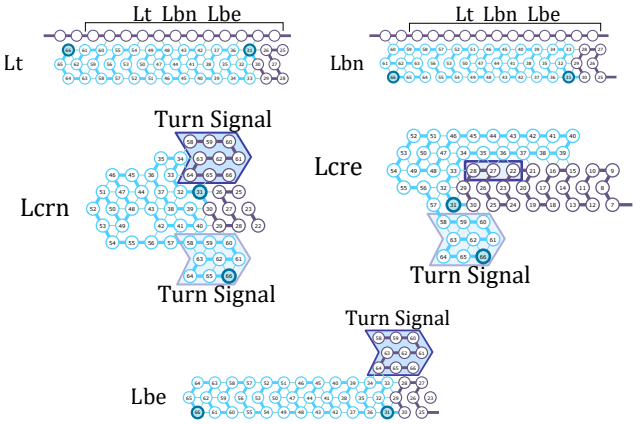

Fig. 5 All the five bricks of module L: `Lt`, `Lbn`, `Lcrn`, `Lcre`, and `Lbe` from top left to bottom right. In zigs, L folds into either `Lt` or `Lbn` depending on where it starts, until the transcript reaches the left end, where L folds either into `Lcrn` if the current count has not been overflowed, or into `Lbe` at an overflow. In the case of overflow, the next L folds into `Lcre`. In zags, L always folds into `Lbn`.

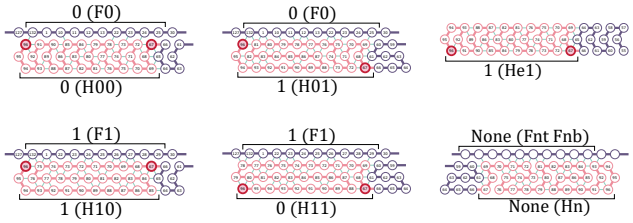

Fig. 6 All the six bricks of module H: `H00`, `H01`, `He1`, `H10`, `H11`, and `Hn` from top left to bottom right. In zags, H always folds into `Hn` while in zigs, it folds into one of the other five bricks.

(F, L, and R) from an instance of H to another for more significant bit. Carry transfers as a height for modules to start. In zigs, modules F, L, and R take the respective two bricks (`Fnt` and `Fnb` for F, `Lt` and `Lbn` for L, and `Rt` and `Rb` for R; see Figs. 4, 5, and 7), both of which start and end at the same height: one at the top while the other at the bottom. A zig is carried by being forced to start at the bottom by the last `Rcr` or the seed. Until the count overflows, module H encounters only four environments, which encode input 0 as w_{F0} or 1 as w_{F1} and carry or no-carry as of whether the module

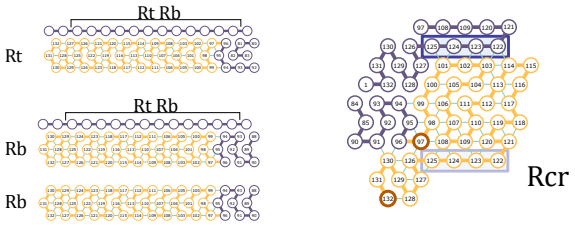

Fig. 7 All the three bricks of module R: `Rt`, `Rb`, and `Rcr`. In zigs, R folds into `Rt` or `Rb`, depending on how high it starts. In zags, R always folds into `Rb` until the transcript reaches the right end, where R folds into `Rcr` due to the four beads (boxed). `Rcr` is provided with this Turn Signal for the next right carriage-return. Note that `Rb` is not bonded to the environment at all. That is, this module certainly folds into `Rb` at an overflow.

starts at the bottom or top, where it takes `H00`, `H01`, `H10`, and `H11`, respectively, as shown in Fig. 6 (`H`xc is folded when the input is x and the carry is given if $c = 1$ or not otherwise).

Let us see how the subsequence $(FLHR)^kF$ folds into a zig in order to count up; for $k = 1$ and the current count 0, see Fig. 8. The zig starts at the bottom, that is, being carried, and the carry transfers through the first instances of F and L in the way just explained toward the first instance of H. This H is thus fed with carry and folds into `H01` if the bit encoded above is 0, as illustrated in Fig. 8, or `H11` if the bit is rather 1. `H01` ends at the top, corresponding to canceling the carry out. This absence of carry transfers through the succeeding modules leftward. As a result, the zig ends, or more precisely an instance of F ends folding at the bottom if this increment causes an overflow (Fig. 10), or at the top otherwise (Fig. 8). An instance of L is to be transcribed next. It folds either into `Lcrn` for (normal) carriage-return unless the count is overflowed, or into `Lbe` at an overflow.

3.4 Bit width expansion at an overflow

The fixed bit-width counter cannot handle a zig that ends at the bottom, that is, its behavior is undefined at an overflow. In contrast, module L in this infinite counter is designed so as to fold into `Lbe` in this situation in order to keep counting up (Fig. 11). Observe that the dent on Turn Signal made of `58`, `63`, and `64` is too far for module L, or more precisely, for its beads `33` and `34` to interact with strongly enough to fold into `Lcrn`. `Lbe` is a self-sustaining conformation (glider) so that it can fold even if nothing is around, which occurs at that very moment. For the same reason, the following instances of H, R, and F fold into self-sustaining conformations `He1`, `Rb`, and `Fnb`, respectively (Figs. 11 and 12). Note that `He1` is essentially the same as `H00`

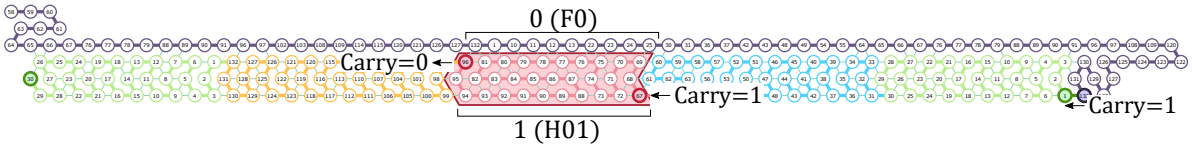

Fig. 8 The first zig. 0 is encoded as an initial count below the seed in the format (2) with $k = 1$ (1-bit width). Being fed with carry, the zig increments the count. Module H outputs 1, or more precisely a sequence of bead types which shall be interpreted as 1 in the next zag and reformatted, as a sum and cancels the carry.

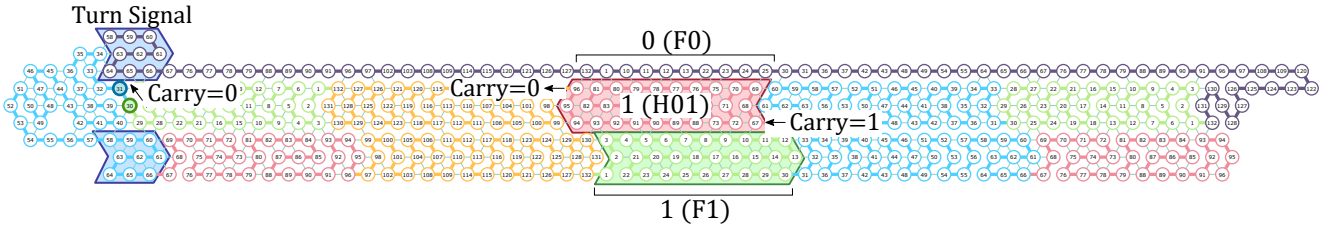

Fig. 9 The first zag. A Turn Signal at the left end of the seed makes module L folds into the brick Lcrn to turn and initiate the zag. This brick is equipped with another Turn Signal for the sake of the next turn. In a zag, module F reads the output of module H from above and formats it for the sake of the next zig.

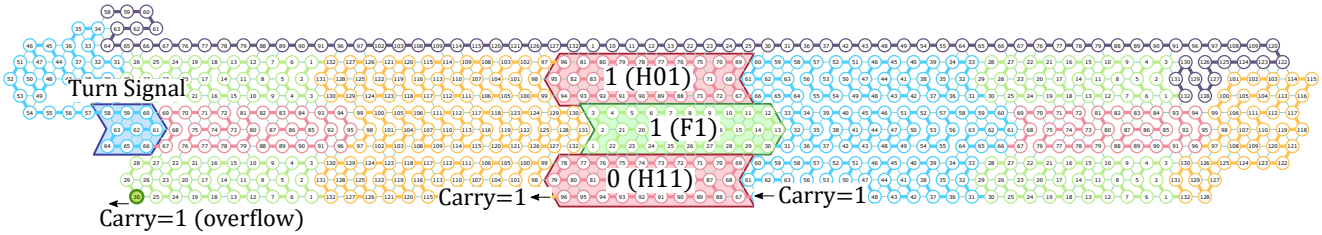

Fig. 10 Overflow. When the carry has not been canceled out until the end of a zig, the Turn Signal is too far for the upcoming module, which is L, to be folded into the brick Lcrn for turn.

but exposes the opposite side downward, which will be interpreted as the leading bit 1 after expansion in the next zag. When the next instance of L is transcribed, there is nothing around. Nevertheless, it does not fold into `Lbe` but folds into `Lcre` for carriage-return; how? It is guided by interaction between the beads `35`, `36` along the transcript of L and the Turn Signal `28-27-22` above `Fnb` (Figs. 5 and 12). This signal is usually hidden geometrically by the previous zag, and hence, does no harm.

3.5 Formatting

The count has been successfully incremented but it is not in the format (2) yet. In the upcoming zag, instances of F play their primary role to format 1 bit output by module H (recall that instances of H and F are aligned vertically and alternately). Both of the bricks of L for carriage-return, i.e., `Lcrn` and `Lcre`, end at the bottom so that zags start at the bottom. All modules start and end at the bottom in zags; note that nothing has to be transferred between modules. That is, instances of H, L, and R fold into `Hn`, `Lbn`, and `Rb`, respectively. Below the brick `H`xc, an instance of F folds into `F`y, where $y = (x + c) \mod 2$.

3.6 Counting from a non-coding seed

The capability of handling overflows enables the system to launch at a simplest possible seed which encodes nothing but a Turn Signal for the first right turn as long as the system starts counting from 0 (see Fig. 13).

3.7 Rule set

The rule set of the proposed counter consists of the following 377 rules:

(1,6),	(13,72),	(29,32),	(65,68),	(88,93),
(1,74),	(13,81),	(29,33),	(65,69),	(89,93),
(1,75),	(14,18),	(29,40),	(65,84),	(91,130),
(1,77),	(14,29),	(29,60),	(67,131),	(91,96),
(1,80),	(14,30),	(29,69),	(67,72),	(92,96),
(1,81),	(15,28),	(30,32),	(67,84),	(93,130),
(1,84),	(15,39),	(30,33),	(67,88),	(93,132),

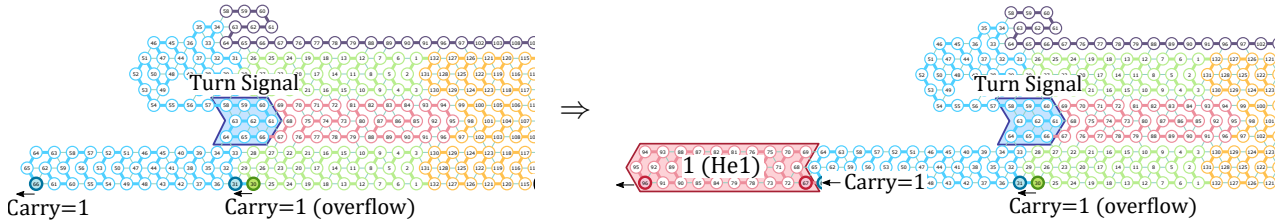

Fig. 11 (Left) Starting from the bottom, the Turn Signal above is too far for this L to fold into `Lcrn`. It rather folds into `Lbe` and initiates bit expansion. (Right) Without anything around, the succeeding H folds into a glider (brick `He1`).

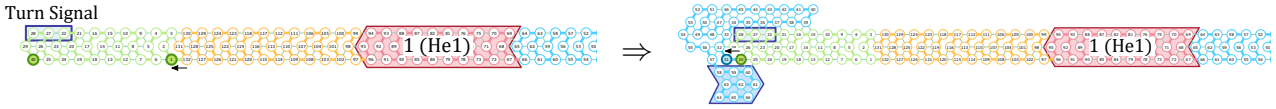

Fig. 12 The succeeding R and F also fold into respective glider-like bricks. (Left) This brick of F (`Fnb`) exposes Turn Signal `28-27-22` (boxed), which is usually "hidden" under the previous zag. (Right) The exposed `28-27-22` (boxed) triggers the folding of next L into a special brick (`Lcre`) for left carriage-return.

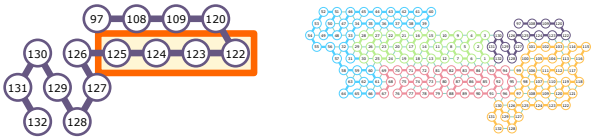

Fig. 13 Counting from a non-coding seed. (Left) The simplest-possible seed that consists only of the boxed right Turn Signal. (Right) Starting from this non-coding seed, the first period results in the count 1 in the 1-bit.

4 Conclusion

In this paper, we have improved the existing finite binary counter by equipping it with a function of bit expansion at an overflow. Applications of this infinite counter include simulation of countably many Turing-machines in parallel for proving the undecidability of various properties of oritatami system, and folding of fractals. For their sake, this counter should be optimized, for example, by reducing bead types, shortening the period, or simplifying its rule set, though such optimization problems are computationally hard in general [11,15].
